**Abstract**

The aim of this work was the evaluation of physiological behavior of *Aspergillus flavus* affected by the application of sub-lethal doses of microencapsulated 2(3)-tert-butyl-4 hydroxyanisole (BHA). For this, peanut meal extract agar (PMEA) and peanut kernels with modified water activity (aw) (0.96 and 0.99) and a sub-lethal dose (0.6 mM) of an BHA formulation was used. Fungal physiological aspects as growth rate, time to growth and AFB1 evolution were modified by the formulation, especially on PMEA at both aw. In general, conidial and vesicle size of the mold only were affected by growth substrate, being higher on sterile seed than on PMEA regardless of aw condition. However, positive correlation (p<0.05) observed in controls between radius and biomass responses was altered by the application of the formulation, mainly under the lowest aw in both substrate evaluated. Finally, presence of encapsulated antioxidant showed significant change in Pearson coefficients respect to the controls for all studied parameters. As conclusion, sub-lethal doses of formulation lead in reduction on growth and toxin accumulation, but conidial and vesicle size were not affected. Results of this work indicate the need to consider both fungal primary and secondary metabolism to determine the effect of food grade antioxidant formulation.

**Keywords**: Peanut, *Aspergillus flavus*, Aflatoxin B1, Microcapsules, BHA

**Introduction**

Peanut (*Arachis hypogaea* L.) is a very important dried fruit considered as one of the most widely used nuts due to their nutritional properties and taste. Some nutritional characteristics studied for this nut and its oil are the high levels of proteins and minerals with a well-balanced fatty acid and antioxidant profiles [1,2]. Besides, this food is very important for the Argentina economy due to the continuous increase in the yield with a total production of 1.17 million tons in 2015/16 harvest season [3]. Moreover, around 0.44 and 0.68 million tons are exported ranking the first position as peanut exporter since 2012 [4]. Due to the economic importance of peanut, quality and safety are essential for marketing. However, is considered to be a high-risk product for contamination with aflatoxins (AFs) due to frequently contaminated with moulds, particularly *Aspergillus flavus* and *Aspergillus parasiticus*, and because of long peanut drying times and occurrence of rainy periods after uprooting [5]. Both aflatoxinigenic fungsares are between the most important storage moulds founded by many studied in stored peanut [6-11]. Particularly, Passone *et al.* [12] reported the prevalence of *Aspergillus* section Flavi aflatoxin producing strains (65 and 75%) on stored peanut in big bags with four different aw levels. Aflatoxin B1 (AFB1) is considered to be a carcinogenic type 1 by the International Agency for Research on Cancer [13]. Mycotoxins can be produced in peanut grains in the field, during transport and storage where conditions are suitable for their production becoming a high risk to human and animal health [14]. Mould growth is commonly controlled using synthetic fungicides; however continuous and indiscriminate use of these chemical compounds in foods and feeds, could lead to toxic effects for consumers and to the development of resistances in microorganisms [15]. One alternative to the use of synthetic fungicides which could lead to persistent residues, carcinogenic and toxic effects is the use of harmless substances, like food grade antioxidant as butylated hydroxyanisole (BHA) (phenolic antioxidant). This compound has shown effect against moulds and insect vectors of aflatoxicogenic fungi on stored peanuts [16-20]. However, is known that levels of BHA decreased with time when it was applied in peanut food system due to the interaction with physical and biological factors [21] (Passone, et al. 2008c). Girardi *et al.* [22] applied BHA microencapsulation technology in order to keep food grade antioxidants from the action of environmental factors. Besides, Garcia *et al.* [23] showed that 20 mm of BHA formulation completely inhibited *Aspergillus* section *Flavi* development and AF aflatoxin accumulation; nevertheless lower dose decreased both growth and toxin levels. In this work, our interest focuses on the physiological behavior of *Aspergillus flavus* affected by the exposure to sub-lethal BHA formulation. To elucidate this impact the aims of this work were i) to assess growth parameters based on radial growth and biomass dry weight; ii) to study evolution of AFB1 and iii) determinate vesicle and conidial sizes under optical microscope, in presence of sub-lethal inhibitory concentrations of antioxidant formulation, at two different water activities (aw) in peanut meal extract agar (PMEA) and peanut grains.

**Material and Methods**

**Fungal isolate and preparation of inoculum**

*A. flavus* (RCP08108) a mycotoxigenic isolate was
included in this research. The reference in bracket is the code of cultures held in the Microbial Ecology Laboratory Collection, Department of Microbiology and Immunology of the National University of Rio Cuarto, Córdoba, Argentina. Isolate was sub-cultured on malt extract agar (MEA) plate and incubated at 25°C for 7 days to enable significant sporulation. After incubation, a sterile inoculation loop was used to remove the conidia from MEA plates and it was suspended in 5 ml of distilled peptone water solution (0.1%). After homogenization, the suspension was adjusted using a Neubauer counting chamber to achieve final concentration of 1–5×10⁴ spores/ml.

**Preparation of antioxidant formulation**
An industrial grade antioxidant, 2(3)-tert-butyl-4-hydroxyanisole (BHA) obtained from Eastman Chemical Company was used as core material. Formulation was made by complex coacervation using gelatin (bloom 240) and Arabic gum as core material following the methodology proposed by Girardi et al. [22]. Empty capsules were performed with the same methodology but without the addition of BHA, in order to be used as control by replacing the core material with peanut oil. Sub-lethal dose of antioxidant formulation (0.65 mm) was used in both culture medium and peanut grains.

**Culture medium and peanut kernels preparation**
Peanut meal extract agar (PMEA) was prepared at 2% (w/v) with a final pH of 6.5. Thirty grams of ground peanut per liter were boiled for 45 min and the resultant mixture filtered through a double layer of muslin. Volume was made up to 1 l and agar-agar at 2% (w/v) was added [24]. Water activity of the basic medium (0.99) was adjusted to 0.96, with known amounts of glycerol [25]. Basic medium was autoclaved at 121°C for 20 min before cooling at 50°C and then poured into 9 cm sterile Petri dishes and microcapsules with or without BHA were added to reach 0.6 mm concentration. Water activity of representative samples of each treatment was checked after autoclaving with an AquaLab Water Activity Meter 4TE with an accuracy of ±0.001 (Decagon Devices, Inc.) Peanut kernels were sterilized by autoclaving at 120°C during 20 minutes twice. Water activity of sterile peanut was adjusted by aseptic addition of distilled water to seeds inside sealed containers which were kept at 4°C for 48 hours with periodic hand-shaking during this time. The amount of water necessary to reach the different aw levels was determined by a calibration curve (water activity-ml vs. water to be added/g substrate) previously made [23]. Therefore, aw of seeds was modified at 0.96 and 0.99 by the addition of 200 and 550 μl/g of sterile water, respectively and checked with the Aqua Lab Water Activity Meter 4TE (Decagon Devices, Inc.). Twenty five g of peanut were poured in Petri plates forming a single layer and the formulation with or without antioxidant was added to reach 0.6 mm concentration.

**Inoculation and incubation**
Petri dishes were inoculated centrally with 2 μl of a 1-5 × 10⁴ spores/ml suspension. Plates with the same aw were enclosed in sealed containers along with beakers containing water glycerol at the same water condition. One hundred PMEA Petri dishes and 90 peanut kernels Petri dishes were inoculated and incubated at 25°C.

**Experimental design**
In this work, a series of PMEA (100) and peanut Petri plates (90) with loaded, unloaded and without BHA microcapsules were prepared at 0.96 and 0.99 aw, and inoculated with A. flavus. PMEA and peanut plates contained 30 ml of medium and 25 g of seeds, respectively. During and after incubation period, Petri plates were analyzed (3 replicates per analysis) for determination of colony radius, biomass weight and AF content, conidial and vesicle size.

**Growth assessment**
Colony radius (mm) and biomass (mg dry weight) were measured at different time periods. Colony radius was daily examined for an overall period of 30 days by measurements at right angles with the aid of a ruler and a binocular magnifier, on PMEA and peanut Petri dishes. Mycelium dry weight was measured as Taniwaki. On culture medium. Colonies were cut from the medium, transferred to a beaker containing distilled water (100 ml approximately), then heated in a streamer for 30 min to melt agar. Mycelium remained intact was collected and transferred to a dried, weighed filter paper and dried at 80°C for 18 hrs. Then the filter paper was weighed and the dry weight of biomass was calculated by difference.

**Aflatoxin B1 analyses from PMEA and peanut seeds**

**Aflatoxin B1 extraction from PMEA:** Three agar plugs (diameter 4 mm) of each colony were removed from center, middle and outer of the colonies at different incubation times and placed in a vial. One ml of methanol was added, and the vials were shaken for 5 s. After 60 min, the extracts were shaken, filtered (Microclar 0.45 μm, MC-NYL-04N), transferred into another vial and stored at 4°C until the analysis by HPLC instrument (Waters, Mildford, MA, SA).

**Aflatoxin B1 extraction from peanut kernels**
Determination of AFB1 in peanut kernels was performed according to AOAC’s official method 994.08 with some modifications. Total AFs were extracted at different times from a representative sample (25 g) of ground peanut with 100 ml of acetonitrile: water (84:14 v/v) for 30 min using an orbital shaker, and the supernatants was filtered through Whatman N°4 filter paper. Then, 5 ml of the extract was applied to a multifunctional cleaned column (R-BIOPHARM Rhone LDT). The filtrate (2 ml) was evaporated to dryness and stored at 4°C until to high-performance liquid chromatography (HPLC) analysis.

**Aflatoxin B₁ detection and quantification**
Aflatoxin B₁ was detected and quantified separately by using a HPLC system (Waters 2696 separations module, Waters, Milford, USA). Aflatoxin B₁ quantification was performed according to Trucksess. with some modifications. Dry extracts were dissolved in 200 μL of acetonitrile: water (9:1) and derivatized with 700 μl of trifluoroacetic acid:acetic acid:water (20:10:70). One hundred μl of the derivatized solutions were inject in HPLC system (Waters 2696 separation module, Waters, Milford, USA) and chromatographic separations were performed on a stainless steel C18 reverse phase column (150×4.6 mm i.d.,5μm particle size, Phenomenex, USA ). Water: methanol: acetonitrile (66.6:16.7:16.7) mixture was used.
as the mobile phase at a flow rate of 1.5 ml/min. A Waters 2475 module was used for fluorescence detection (λexc 360 nm; λem 440 nm). Quantification was achieved with a software integrator (Empower, Milford, MA, USA). The mycotoxin was quantified on the basis of the HPLC fluorimetric response compared with that of a range of mycotoxins standards. Detection (LOD) and quantification (LOQ) limits of the analytical method were 1.5 ng/g and 4.5 ng/g, respectively.

Conidial and vesicular size evaluation

Size of conidia and vesicles of A. flavus were examined at the final of the assay (20 days) by optical microscopy at 40x magnification (Carl Zeiss, 37081). Diameters of one hundred conidia and twenty vesicles were registered for each treatment. Images were captured and size was estimated by using Motic Images Plus 2.0 (2005) software.

Statistical analysis

Diameters of growing colonies were plotted against time and Barany and Roberts model was used to estimate growth rate and time to growth for each condition. Analysis of variance of growth rates, time to growth, conidial and vesicle size and AFB, accumulation was used in order to assess significant differences due to growth conditions and BHA formulation assayed. Mycotoxins were expressed as ng/g of culture medium or peanut. LSD test was used to establish the differences among mean values of the variables under the different levels of factors at p<0.05. Pearson correlation coefficient was used to evaluate correlations between studied factors.

Results

A. flavus (RCP08108) growth assessment growing on PMEA and peanut seeds treated with BHA formulation

Analysis of variance (ANOVA) was performed to determine the effect of growth substrate (Gs), treatment (T), (a<sub>G</sub>) and their interactions on fungal growth in culture medium through both colony radius and biomass assays. On the one hand, all factors alone and their interactions affected significantly (p<0.01) both mould growth parameters estimated from colony: radial “growth rate” [µ (mm/d)] and “time to growth” [λ (days)]. Growth rate was highly affected by a<sub>G</sub> (p<0.1 and F=71.23) followed by Gs (p<0.1 and F=19.56) and T (p<0.1 and F=3.4). While λ was greatly affected by Gs (p<0.1 and F=150.50) and T (p<0.1 F=26.5). On the other hand, both growth parameters obtained from biomass dry weight also were affected by a<sub>G</sub> and T (a<sub>T</sub>, p<0.1; F=104.93 and T, p<0.1; F=5.50 for µ and a<sub>G</sub>, p<0.1; F=12.12 and T, p<0.1; F=119.03 for λ). Table 1 shows the effect of microencapsulated BHA at sub-inhibitory level of 0.6 mm on radial µ (mm/d) and λ (days) values estimated from radial growth and biomass dry weight assays on PMEA and peanut kernel conditioned at different a<sub>G</sub> (0.99, 0.96). Results showed that on PMEA, for each a<sub>G</sub> assayed, both growth parameters on radial experiments revealed significant differences between control without capsules (CWC) and BHA formulation (F-BHA) or control with empty microcapsules (CEC), according to LSD test (p<0.05). With this respects, application of microcapsules (with or without antioxidant) modified radial µ and λ in culture media where caused a reduction in µ and an increase in λ in the order of 20 and 50%, respectively, for the both studied water conditions compared with CWC. However, no significant differences (p>0.05) for µ parameter estimated trough biomass assay where found, while λ show a decrease of 90% when mould grew in presence of BHA capsules, regardless a<sub>G</sub>. As for biomass dry weight, growth studies performed on peanut kernels did not showed significant differences (p<0.05) for µ between treatment and controls samples at the both a<sub>G</sub>, but λ parameter was significantly increased (48%) by the presence of microcapsules in the substrate.

Conidial and vesicular size of A. flavus (RCP08108) affected by BHA formulation in culture media (PMEA) and peanut kernels

Effects of single factor as well as their two and three way interactions on conidial and vesicle sizes for both culture media and peanut kernels were determined by ANOVA. Conidial diameter was only affected by Gs (p<0.1 and F=11.3), while vesicle diameter was affected by a<sub>G</sub> conditions (p<0.1 and F=7.37) and its interaction with Gs (p<0.1 and F=10.37). Conidial and vesicular size of A. flavus (RCP08108) that developed on PMEA and peanut kernels modified at 0.96 and 0.99 a<sub>G</sub> in presence of microencapsulated BHA, CEC and CWC at the end of the experiment (20 days) are shown in Figure 1A and 1B. No significant differences (p>0.05) between conidial size estimated in treatment (mean=9.4 μm and 11.3 μm for PMEA and peanut kernels, respectively) and control samples (mean=9.4 μm and 11.5 μm for PMEA and peanut kernels, respectively) were found (Figure 1A). However, conidial diameters were significantly higher in peanut kernels than in PMEA according to LSD test (p<0.05) by recording mean sizes of 11.5 and 9.5 μm respectively. Besides, water conditions significant affected (p<0.05) size of the spores on PMEA where

*Fungal growth rate: cm of colony days -1.

Footnotes:

1: Fungal colony diameter (cm) in WBM agar medium with or without preservatives after 10 days at 30°C. Variables with the same superscript letter in the same column show no significant differences between them (P>0.05).
and controls were found, except for the kernels at 0.99 a
assayed. No significant differences (p<0.05) between treatment
period (20 days) was statistically affected by Gs (p=0.00 and
F=12.6); (Gs*T; p=0.00 and 
F=14.01) and (Gs*a,T; p=0.01 and 
F=7.04). For the two a
assayed, AFB, levels detected in controls were significantly higher respect to BHA treatment according to LSD test
(p<0.05), regardless of substrate evaluated. On the one hand,
when AFB, accumulation on PMEA-CWC was evaluated,
levels of this metabolite sharply increased in the order of
6437.6 and 3150.5 µg/g at 0.96 and 0.99 a,w; respectively,
after 14 days of incubation, being statistically higher (p<0.05)
(50%) at the lowest water stress condition (0.96) (Figure
1B). A. flavus strain growing in presence of CEC produces a
pick of AFB, at 11 and 14 days of incubation at 0.96 and
0.99 a,w; respectively, being the levels lower (1.7 to 2.5 times)
respect to CWC during all incubation period, regardless of
substrate a,w. Similar trend of toxin accumulation was found
when fungus grew in culture medium that with the addition
of microcapsules, showing levels of 2105.2 µg/g at 0.96 a,w
and 1491.9 µg/g at 0.99 a,w at the end of the assay. On the
other hand, levels of AFB, on peanut kernels in CWC showed
a gradual increase of the toxin until 11 days where a decline
occurred for both a,w. Final levels detected were 6361.2 and
7180.6 µg/g at 0.96 and 0.99a,w., respectively. For CEC and
F-BHA, toxin evolution was dependent of a,w condition. In
the case of CEC, at 0.96 a,w, AFB, accumulation was increased
with time except at 11 days where a decreased of 60% was
observed compared with 7 days. At this a,w condition, mean
level estimated was14286.5 µg/g at 20 days of incubation.
Although at 0.99 a,w a production pick of 9084.1 µg/g was
observed at 7 days and levels registered at the end of the
experiment (20 days) were 3 times lower (5311.2 µg/g)
compared with the lowest water condition (0.96). Finally,
production pattern of the toxin in presence of F-BHA at 0.96
a,w showed a sharp increase at 7 days of incubation and this
level was maintained around of 11122.5 µg/g until 20 days
where a decline of the toxin accumulation was found (6935.8
µg/g). However, at the highest water condition (0.99) AFB, was
increasing with time showing a production pick at 7 days
(8227.1 µg/g) with a mean final level of 6259.5 µg/g.

Correlation among studied parameters of A. flavus
(RCP08108) for BHA formulation and controls

Pearson correlation coefficients of the experiments were
performed on PMEA and peanut kernels for AFB, accumulation,
colony radius and biomass dry weight through experimental
time to evaluate toxin evolution together growth (Table 2).
Respect to PMEA assay, for both radius (mm) and biomass dry
weight (mg) a significant positive correlation (p<0.05) was found only
for CWC at 0.96 a,w. However, for the highest water condition
(0.99) all treatment presented positive correlation except for
mycelial weight under CEC treatment. Regarding experiments
performed on peanut, only significant positive correlation
(p<0.05) between colony radius and AFB, accumulation was
found for CWC at both a,w.

On the other hand, Pearson correlation coefficients between

Figure 1. Effect of calcium propionate (A) and potassium
sorbate (B) at different pH on production of ochratoxin A by
Aspergillus niger 13D at pH 5.0, 5.5 and 6.0. White bars: pH 5;
grey bars: pH 5.5; black bars: pH 6. Variables with the same
superscript number in the same condition (classification
variable: preservative concentration) show no significant
differences between them (P<0.05). Variables with the same
superscript number in the same condition (classification
variable: pH) group show no significant differences between
them (P>0.05).

Table 2. Percentage of undissociated organic acid related to the pH.

distances around of 15% were found between 0.96 a,w and
0.99 a,w. However, when A. flavus grew on peanut substrate,
size of conidia was independent of the kernel water condition.
Figure 1B shows that vesicle size was not influenced by the
water condition of peanut based agar with a mean diameter of
98 µm. Nevertheless, when A. flavus developed on peanut
kernels, size of vesicle was 40% higher at the lower a,w (0.96)
assayed. No significant differences (p<0.05) between treatment
and controls were found, except for the kernels at 0.99a,w where
fungus developed vesicles 32% higher in presence of F-BHA
formulation and CEC compared to CWC.

BHA formulation effects on trend of AFB, accumulation
by A. flavus (RCP08108)

ANOVA test of the effect of Gs, a,w and T and their interactions
showed that accumulation of AFB, at the final of incubation
period (20 days) was statistically affected by Gs (p=0.00 and
F=134.2), a,w (p=0.00 and F=52.2), T (p=0.00 and F=28.9)
and their two and three way interactions [(Gs*a,w; p=0.00 and
final levels of AFB₁, conidial and vesicle size recorded on PMEA and peanut kernels were estimated for treatment and controls. No correlations were found in controls (CEC and CWC) for the fungal parameters studied. However, BHA formulation showed a significant positive correlation (p<0.05) between AFB₁ versus conidial size. No significant correlations were found between AFB₁ versus vesicle size and conidial versus vesicle size.

Discussion

Antifungal and Antiaflatoxigenic effect of free and microencapsulated BHA against A. flavus and aflatoxin accumulation has been demonstrated in previous works [16-20,23]. In the present article we were focused to assess the physiological behavior of A. flavus (RCP08108) in presence of a sub-lethal dose (0.65 mm) microencapsulated food grade antioxidant. For this, the mould was exposed to BHA formulation on culture medium and peanut kernels conditioned at two different aw. With this respect, our results showed that growth parameters of A. flavus obtained in this research were affected by all studied factors (aw, Gs and T) except λ which was not influenced by aw. For both PMEA and peanut kernels, growth of the mould decreased by the presence of empty microcapsules and antioxidant formulation with similar data of growth between them. This is agreeing with results founded by Garcia et al. [23]. Which conclude that wall material of microcapsules impart specific properties of the coating increasing antifungal effect. Our data showed a reduction of μ and increase in λ in presence of microencapsulated BHA being growth higher on peanut kernels than on culture medium. This reduction in mould growth due to the addition of a low dose of microencapsulated BHA is agree with Passone. which studied the effect of sub-lethal doses of a mix of BHA:BHT (1+1 mm and 5+5 mm) against A. parasiticus and A. flavus Besides, there are many works that studied the effect of aw on A. flavus under different culture media and grains [14,24] Most of these works found that low levels of aw produce a decrease of growth mould and that growth parameters were different between culture medium and kernels. For this, it is necessary to evaluate Eco physiological behavior of aflatoxigenic strains in food system where exist other factors such as kernel components: fat, carbohydrate, protein, salt and pH which could influence in the effectiveness of the antimicrobial potency Klich and Pitt taxonomy described A. flavus conidial size between 3-6 µm in Czapek Yeast extract agar (CYA). However this fungal feature in our work was around 50 and 63% higher in PMEA and peanut kernels respectively, compared with the above reference. Besides, conidial size was not affected by the presence of microcapsules but values were different among growth substrates with the highest diameters in kernels. With respect to vesicle, formulation only affected its size when A. flavus grew in peanut kernels conditioned at the highest aw (0.99), where values obtained for controls were similar to those reported in Klich and Pitt. Meanwhile, vesicle sizes of A. flavus estimated in presence of F-BHA were 50% lower than in this absence. At the lowest water condition (0.96 aw), diameters of vesicle were similar between treatments but doubled their size at the highest aw condition. As our knowledge, there are no researches which evaluated the effect of chemical agent on conidial and vesicular magnitude of A. flavus. However, it is important remark that, conidial cell born from conidiophore being responsible to the propagation of the fungus to new habitats giving rise to new individuals. Besides, sporulation processes is commonly associated with toxic metabolites production. Regarding AFB₁ accumulation in this work level of this toxin detected at the end of the experiment were between 1-6.4 times higher in peanut kernels than in PMEA coinciding with μ and conidial diameters increases. May be, this is because AFB₁ is related to secondary metabolism which is commonly associated with sporulation processes in molds. Thus toxin is secreted by growing colonies together conidia development. Besides, samples treated with F-BHA presented the lowest levels of the toxin for both growth substrate and aw. However, previous studies suggest that sub-inhibitory antioxidant levels carried out to aflatoxin production stimulation. In particular, Passone. founded high levels of the toxin accumulation and an induction in aflD gene expression involved in aflatoxin biosynthesis of A. flavus in PMEA when a sub-lethal dose of BHA and butylated hydroxytoluene mixture (1+1 mM) was used. On the other hand, toxin evolution for CWC was different from CEC and F-BHA regardless of substrate and water availability. For CWC, toxin accumulation by A. flavus increased parallel with the expansion of the colony radius regardless of growth substrate according to the significant positive correlation evidenced by Pearson analysis. A. flavus (RCP08108) behavior registered in CWC was also observed by Garcia et al. [25] in maize and maize agar medium (MAM) for AFB₁ and AFB₂, where toxin accumulation increased together with growth of the isolate. However, for CEC and F-BHA treatments, toxin levels tended to decrease over time. Therefore, a lack of significant correlation was observed by the presence of both types of microcapsules (full or empty). Besides, a not clear trend of Pearson coefficients for AFB₁ accumulation versus biomass dry weight was observed. However, Mellon and Garcia reported that AFB₁ accumulation parallel increased with fungal biomass in liquid based maize, medium agar maize (MAM) and maize kernels. By contrast, Shih and Marth, observed that aflatoxin production generally increase during the logarithmic and deceleration phases of fungal growth, suggesting that toxin is either a metabolite produced by growing hyphae or is converted biosynthetically from some other compounds by growing hyphae. It may expect that production of mycotoxins, as secondary metabolites, to follow a curve paralleling that of growth but slightly delayed, however regulation of secondary metabolism is poorly understood and the relationship between the rates of primary and secondary metabolism is not clear. Finally, correlations among growth features of A. flavus showed differences when Pearson correlations were evaluated for controls and F-BHA. No correlations were found for the both evaluated controls between AFB₁, conidial and vesicle size. However, a significant positive correlation between AFB₁ and conidial size was found for the F-BHA treatment. Nevertheless, no correlation was observed when all fungal parameters and treatment were integrated for Pearson analysis. As conclusions, presence of F-BHA sub-inhibitory effect could lead in changes in growth parameters as μ, and λ, also altering A. flavus toxin evolution with time by modifying final concentrations, regardless of substrate. Results of this work indicate the need to consider both fungal primary and secondary metabolism to determine the effect of food grade antioxidant formulation allowing us to

J Food Technol Pres 2016 Volume 1 Issue 1
predict that there are no risks in the estimation of aflatoxins in those areas of the storage system where F-BHA could not be distributed homogeneously.
