In the present case control study, serum paraoxonase activity and oxidative stress were monitored in 100 patients with AMI and 50 age and sex matched healthy controls. The levels of total cholesterol, triglycerides and low density lipoprotein were significantly (p<0.001) high and the levels of high density lipoprotein were significantly (p<0.001) low in the AMI patients as compared to healthy controls. MDA level was significantly (p<0.001) high and antioxidant activity of PON was significantly low in diabetic (p<0.001) and non-diabetic (p<0.01) AMI patients as compared with controls. Our findings show the increased oxidative stress and decreased paraoxonase antioxidant activity in AMI patients and importance of assessing these markers along with lipid profile in AMI patients.

Key Words: Oxidative stress, Coronary artery disease, AMI, Paraoxonase.
study was carried out in Hamidia Hospital attached to Gandhi Medical College, Bhopal, India. Fasting blood samples were collected from both controls and patients for a series of laboratory investigation using standard protocols.

The study was approved by the Institutional Ethical Committee, for biomedical research.

Exclusion criteria
Patients with renal insufficiency, hepatic disease, or taking lipid lowering drugs or antioxidant vitamin supplements were excluded from study.

Estimation of lipid profile
Fasting lipid profile was done in all subjects. Serum Cholesterol, HDL-C, VLDL-C were determined by CHOD-PAP method (Roche Diagnostics). Serum Triglyceride was measured enzymatic GPO-POD method (Roche Diagnostics). LDL-C calculated by using Friedewald Formula. (LDL = total cholesterol -1/5 Triglycerides – HDL) [9].

Estimation of MDA
MDA was estimated by colorimetric method of Satoch K. et al. In this method, 2.5 ml of 20% trichloroacetic acid and 1.0 ml of 0.67% TBA are added to 0.5 ml of serum, then the mixture is heated in a boiling water bath for 30 min. The resulting chromogen is extracted with 4.0 ml of n-butyl alcohol and the absorbance of organic phase is determined at the wavelength of 530 nm. The determined values are expressed in terms of malondialdehyde (nmole/ml) used as reference standard – 1, 1, 3, 3-tetraethoxypropane [10].

Estimation of serum paraoxanase activity
Paraoxonase was estimated spectrophotometrically by the method, described elsewhere with modification [11]. Briefly, the assay mixture consists of 500 µl of 2.2 mmol/l paraoxon substrate in 0.1 mol/l Tris-HCL buffer, pH 8.0 containing 2 mmol/l CaCl2 and 50 µl of fresh serum. After mixing the contents, kinetics measurements were taken immediately at every minute for five minutes, at 405 nm at 25 C. First absorbance reading is taken as 0-minute reading and subsequent absorbance readings were taken as one minute to four-minute readings. Corrected absorbance reading were obtained by subtracting 1 minute reading with 0 minute reading, likewise, the latter minute reading was subtracted with the previous minute reading. The mean absorbance was calculated. Mean absorbance was used to determine PON1 activity, and standard graph plotted using 1 mM P-nitrophenol. PON1 activity was expressed in international units (IU). One IU was defined as 1 µmol of p-nitrophenol formed/min/L at 25 C.

Limitation of study:
Patients included in the present study were admitted in Intensive Cardiac Care Unit (ICCU) of Medicine Department. This study was subjected to 100 AMI Cases within 40-75 years. The laboratory of Biochemistry department is well equipped with semiautoanalyzer, colorimeter and spectrophotometer; hence all investigation were carried out on auto analyzer and spectrophotometer. All investigation methods used in this study were standardized in our laboratory.

Statistical analysis
All the data were analyzed by using the SPSS version 10.0.

Values presented are means ± standard deviation (SD). To test the significance between the study group and the control groups were analyzed by a student’s t - test. The p-value (p<0.05) was considered significant.

Results
Table 1 shows the distribution of risk factors in 100 AMI patients in this study.

Table 2 shows the demographic and clinical characteristics of patients and normal healthy controls. Among 100 AMI patients, 70 were males and 30 were females. Among 50 controls 40 were males and 10 were females. There are 35 AMI patients with obesity and only 10 controls were obese. Diabetic AMI patients had mean age 61.2±14.63 years. Non-diabetic AMI patients had mean age 63.1±14.10 years and controls had mean age 65.0±14.63 years. BMI was significantly high in diabetic AMI group (p<0.001) as compared with control. Systolic blood pressure was significantly high (p<0.001) in both the AMI patients (DM &NDM) as compared with controls.

Table 3 shows the biochemical characteristics of patients and normal healthy controls. Blood lipid parameters- total cholesterol, triglyceride, LDL, were significantly (p<0.001) more increased and HDL was significantly increased.
Serum paraoxonase activity & oxidative stress in acute myocardial infarction

(p<0.001) more decreased in diabetic AMI patients as compared with controls.

Table 4 shows the serum paraoxonase activity and MDA level in AMI patients and normal healthy controls. Serum paraoxonase activity was significantly (p<0.001) more decreased in diabetic AMI patients and MDA level was significantly (p<0.001) more increased in diabetic AMI patients as compared with control group.

### Discussion

The root cause of AMI is mainly atherosclerosis. Oxidative stress, arising as a result of an imbalance, between free radical production and antioxidant deficiencies, is associated with damage to a wide range of molecular species, which includes lipid and lipoproteins also. Atherosclerosis is a process for which there is substantial evidence of a role for oxidative stress. Hypercholesterolemia is universally accepted as a major risk factor for atherosclerosis, but at any given concentration of plasma cholesterol, there is variability in the occurrence of cardiovascular events, as it has been shown that the oxidative modification of LDL might be a crucially important step in development of atherosclerotic plaque [12].

Biomedical Research 2011 Volume 22 Issue 2
In the present study, serum PON1 activity was significantly decreased in AMI patients. This reduction in PON activity might play a central role in the atherosclerotic process, because HDL-PON activity modulates the susceptibility of HDL to atherogenic modifications such as glycation and homocysteinylation [13,14]. PON1 activity associated with HDL-C in plasma is thought to protect LDL-C oxidation [15]. Several studies have shown that PON1 protects low density lipoprotein (LDL) and HDL against oxidative modification. It can destroy active lipids in mildly oxidized LDL and thereby protect against the induction of inflammatory responses in arterial wall cells. Oxidation of LDL is recognized as an early stage in the development of atherosclerosis, leading to LDL uptake by the macrophage scavenger receptor and hence to formation of foam cells [16,17]. Factors influencing serum levels of PON1, either genetic or environmental, will in turn affect the capacity of HDL to protect LDL from oxidation and, consequently, may be linked to atherosclerosis [18]. This is of particular relevance to diabetic patients where higher risk of oxidative stress is suggested to contribute to the greatly increased incidence of vascular disease and other complications [19].

Significant rise in MDA levels (p<0.001), a lipid peroxidation product, in our patients is indicative of elevated oxidative stress in AMI patients. This is similar to work of Dubois Rande et al [20] and Mc Murray [21] that showed a decrease in antioxidant enzyme activities and increase in lipid peroxidation products (MDA) in patients with unstable angina and chronic heart failure.

Many study demonstrated a direct association between diabetes and heart failure [22]. CAD occurs due to a number of factors in diabetics; both insulin resistance and elevated lipid levels, common in diabetes primarily triggers atherogenic injury. It is also suggested that endothelium in diabetic arteries is more prone to atherogenic injury due to increased production of endothelial nitric oxide, known to be antiatherogenic, and increased production of plasminogen activator inhibitor [23].

In conclusion, despite comparable lipid profile, we found significantly low serum PON activity and increased MDA levels in patients with AMI. The rise in MDA and decreased activity of serum PON more in diabetic AMI patients suggesting the important role of diabetes in the development of atherosclerosis and finally AMI. We hypothesize that reduced PON activity and increased MDA level may contribute to the increased susceptibility for the development of AMI. The present study confirms that there is an elevated oxidative stress reduced antioxidant capacity of PON in AMI patients compared to controls emphasizes the importance of assessing these markers for early diagnosis and therapeutic interventions.
