Abstract

Background: Ovarian oogenesis is under the control of gonadotropins. In the human ovary, each fully grown oocyte resumes maturation in response to gonadotrophins. This process is completed after oocytes reach metaphase stage of second meiotic division (MII) stage. The aim of this prospective, clinical trial was to perceive the age and BMI effect on oocytes maturation and embryos development in women undergoing control ovarian hyperstimulation.

Method: A total of 40 infertile women undergoing ovarian hyperstimulation their age range between 18-40 y old were included in this study using two type of protocol: long agonist and antagonist.

Result: Significant negative correlation was observed between the age and the number of retrieved MII oocytes. Significant negatively effects of the BMI on the number of MII oocytes while significant positive correlation between the BMI and the fertilization rate was noticed.

Conclusion: There are negative effects of age and BMI on the oocytes number and quality.

Keywords: Oocyte maturation, Embryo development, Age, BMI.

Introduction

The highest fertile capacity of women is in the age group between 20-24 y; after that a progressive decrease of fertility occurs with age [1]. The decline in female fertility begins several years before menopause, even with continual regular ovulatory cycles [2]. Fertility peaks when a woman is in her late teens and early twenties and begins to decline at age thirty, dropping more rapidly after age 35 y then fertility plummets after age 40 and pregnancy after age 45 is rare [2].

It is well recognized that the fertility potential of women decreases with increasing age. The decline in female reproductive capacity with increasing age has two main causes: Gradual depletion of oocytes from the ovary, and a decrease in oocyte quality [3].

The reproductive organs of the human female exhibit a rate of ageing that is much faster than that of the other body systems, the same picture emerges from IVF studies where female age is undoubtedly the most significant factor influencing clinical outcome [4]. Ovarian functional decline with ageing has been so far extensively characterized in terms of gradual depletion of ovarian follicles and reduced ability to produce oocytes competent for fertilization and further development [5].

A fully developmentally competent oocyte is an oocyte that through oogenesis achieves the ability to resume meiosis, become fertilized with a single spermatozoa, decondense the sperm head, create two pronuclei (PN), pass cleavage stages, undergo maternal to embryonic transition, reach the blastocyst stage, hatch, and establish a pregnancy that results in the birth of a healthy baby [3].

Higher risks of infertility have been found in both overweight and underweight women [6]. BMI is a calculated measurement that compares a person’s weight and height and it is defined as the weight in kilograms divided by the square of the height in meters (kg/m²). The World Health Organization (WHO) and the National Institutes of Health (NIH) describe underweight as a BMI<18.5, normal weight as BMI 18.5-24.9, overweight as BMI 25-29.9 and obesity as BMI>30 [7].

Materials and Methods

This Prospective clinical trial involved patient who were undergoing controlled ovarian hyperstimulation during period of study between August 2016 and February 2017 in outpatient department of high institution for infertility diagnosis and Assisted Reproductive Technologies, Al-Nahrain University, Baghdad-Iraq were recruited in this study.

The present study involved 40 Iraqi infertile women aged (18-39 y) who were undergoing controlled ovarian hyperstimulation.
Full history and all details of protocols were taken from the patients and weight and height measured for Body Mass Index (BMI) calculation.

**Statistical analysis**

Statistical analysis was performed by using statistical package of science (SPSS); version 17.0 and Microsoft excel worksheet 2010.

The numerical data analysis was done by using correlation, unpaired sample t-test for tables. The significance of the differences between values was considered statistically significant at the level of (p<0.05). The descriptive measure of association in a correlational study is "correlation coefficient" (r) which ranges from (-1) to (+1).

If r=-ve-->inverse association, if r=+ve-->+ve association and if r=0-->no association.

Fertilization rate calculation was done by dividing the number of fertilized oocytes to the total number of MII oocytes that undergoing ICSI then the result multiplied to 100.

Fertilization rate=(number of fertilized oocytes/total number of MII oocytes that undergoing ICSI) × 100.

**Basic steps in the ICSI**

The ICSI and embryo transfer process include stimulating the development of healthy ova in the ovaries, ova collection, sperms collection, as well as monitoring the fusion of the ova and selected sperm in the laboratory after intracytoplasmic injection by providing the suitable environment for fertilization and early embryo growth and finally followed by transferring the embryos into the uterus.

**Control ovarian hyperstimulation (COH)**

Two types of COH protocols are involved in this study:

The long GnRH agonist protocol: The long GnRH-agonist protocol for COH included down-regulation of pituitary gland with subcutaneous injection of GnRH-agonist (0.1 mg/d) that was begun on 21st d of the preceding menstrual cycle, then gonadotropin injection administered subcutaneously on the 2nd or 3rd d of menstruation at different dosages according to the patient’s age and previous response of ovulation induction. When at least three follicles had reached 18 mm in diameters HCG injection (10,000 IU) was used for triggering were applied 34-36 h prior to oocytes retrieval [8]. The antagonist protocol included administration of gonadotropin on the 2nd or 3rd d of menstruation at different dosages according to the patient’s age and previous response of ovulation induction then down-regulation of pituitary gland with SC injection of GnRH antagonist when follicular size reached 14 mm in diameter then triggering were applied 34-36 h prior to oocytes retrieval [9]. The COH was monitored by both serum E2 levels and transvaginal ultrasound [9].

Oocyte preparation and maturity assessment:

The retrieved oocyte-corona-cumulus complexes were immediately classified according to their maturity by the embryologist. The cumulus oophorus and the corona radiata were removed from oocytes within 3 h after follicular aspiration. After denudation of oocyte a rapid morphological evaluation by an inverted microscopic is performed, including evaluation of the zona pellucid, cytoplasm, and perivitelline space for any abnormality, and evaluation and grading according to nuclear maturity as metaphase II (MII), metaphase I (MI), or prophase I (GV). Oocyte nuclear maturity, as assessed by light microscopy, is assumed to be at the MII stage when the PBI is visible in the PVS and it is characteristic of metaphase of the second meiotic division, whereas the presence of an intracytoplasmic nucleus called the ‘germinal vesicle’ (GV) which is a characteristic of prophase I of the first meiotic division. The oocytes that have neither a visible GV nor PBI these oocytes are generally classified as MI oocytes.

ICSI and embryo culture: ICSI was performed 3-6 h after oocyte recovery. After removal of cumulus and corona cells, these oocytes were examined under inverted microscope and only oocytes at MII stage that did not show obvious signs of degeneration were used for ICSI.

The injected oocytes were cultured at 37°C and were covered by mineral oil in IVF medium and incubated in an atmosphere of 5% O2, 5% CO2 and 90% N2. The fertilization was assessed 16-20 h after ICSI. The normally fertilized oocytes were considered only for final embryo transfer. These were cultured for an additional 24-30 h at 37°C in fresh CO2-equilibrated IVF medium.

Embryo grading: After ICSI the fertilization and quality of embryo were assessed by the embryologist via the embryo grade. In brief, embryo grading on days 2 and 3 (48 and 72 h after oocytes pickup) was depend on number, size, and symmetry of blastomeres in addition to the percentage of fragmentation.

Embryos were graded morphologically as follows:

Grade 1, symmetrical with equal-sized blastomeres and <10% extracellular fragmentation.

Grade 2, with unequal blastomeres and <10% extracellular fragmentation.

Grade 3, unequal blastomeres with 10%-50% extracellular fragmentation.

Grade 4, >50% blastomeric fragmentation with uneven blastomeres [12].
Results

Table 1 illustrates the correlation of age with laboratory IVF parameters. Significant negative correlation was observed between the age and the number of MII oocytes that retrieved (p value=0.037, r=-0.331) while no significant correlation was detected between the age and all other laboratory IVF parameters.

As demonstrated in Table 2, significant negative effects of the BMI on the number of MII oocytes (p value=0.049, r=-0.313) while significant positive correlation between the BMI and the fertilization rate was noticed (p value=0.042, r=0.323). However no significant effects of the BMI on the other laboratory IVF parameters were observed.

Discussion

The reproductive organs of the human female exhibit a rate of ageing that is much faster than that of the other body systems, the same picture emerges from IVF studies where female age is undoubtedly the most significant factor influencing clinical outcome [4]. Ovarian functional decline with ageing has been so far extensively characterized in terms of gradual depletion of ovarian follicles and reduced ability to produce oocytes competent for fertilization and further development [5].

In this study, Table 1 demonstrates a significant adverse effects of the age on the number of mature oocytes (MII), in addition the number of good quality embryo decrease as the age increase while no effect of age on the other IVF parameters.

Some studies shows that there is a significant effect of age on the expression of genes involved in cell cycle regulation (e.g. microtubule-based processes, chromatin assembly, M-phase of the meiosis) in oocytes in metaphase II (MII) from women undergoing IVF or ICSI treatment, these findings supported that meiosis and cell cycle regulation mechanisms may be affected by increasing age of the woman [13]. In addition, at various developmental stages, follicles behave differently in response to factors promoting follicular cell proliferation, growth, differentiation and apoptosis and very few reach ovulation [14].

Thus, based on the above observations the analysis of the molecular and cellular aspects of follicle ageing would require careful consideration of some main points. First, oocytes and granulosa cells of primordial follicles might remain in a 'resting' phase for a long time, thus behaving as post-mitotic cells which can be required to start growing after 10-50 y. Second, both primordial and growing follicles become exposed to environmental factors related to the ageing of the ovarian somatic compartment. Third, the development of a competent oocyte intimately depends on the cross-talk between all compartments in the ovary.

The present data illustrate that the fertilization rate was not influenced by the increasing age of the women in ICSI. In addition our study shows a tendency towards decreased number of G1 embryo with increasing maternal age further supports that the 2nd meiotic division may be influenced by age, since a recent publication comparing two age groups reports increased time to 2nd polar body extrusion after ICSI in aged women as compared to younger women [15]. In contrary other studies has been found that embryo quality is not affected by women’s age [16].

Obesity has become a major health problem across the world. In women, it is known to cause anovulation, sub-fecundity, increased risk of fetal anomalies and miscarriage rates [17]. However, in women going for assisted reproduction the effects of obesity on egg quality, embryo quality, clinical pregnancy, live birth rates are controversial. Reduced fecundity in obese women is probably related to multiple factors including aberrations in endocrine and metabolic functions that in turn can affect follicular growth, implantation and development of a clinical pregnancy [17].

The results presented in this study assumed an adverse effect of BMI on the oocytes maturation and fertilization rate while no effects on the number of retrieved oocytes, immature oocytes and G1 transferred embryos, as shown in Table 2. The retrieved mature oocytes and fertilization rate decrease with
increasing the BMI and confirm the findings of published reports with some investigator [18,19]. This result was already found in experiments conducted in mice fed with a high fat obesogenic diet, reporting oocytes with delayed maturation and decreased developmental competence in addition it has been demonstrated that these problems with oocyte function are a direct result of a mitochondrial dysfunction. In fact, a high fat obesogenic diet leads to abnormalities of mitochondrial morphology, mitochondrial distribution within the oocyte, metabolism and spindle formation within the oocytes [19]. While the other investigator explains it as obese women required increased doses of gonadotropin for inducing ovulation or stimulating the ovaries to obtain mature oocytes and impaired ovarian responsiveness to gonadotropin stimulation were reported to be associated with obesity [20].

Several investigators have found a decrease in the number of retrieved oocytes in overweight and obese compared with normal weight women, most likely due to decreased response to control ovarian hyperstimulation with increased BMI, whereas others have found no difference [17,20-22]. Other authors have noted an increased frequency of cycle cancellation due to insufficient follicular development [22,23].
