Abstract

The purpose of this study was to determine the remote after-effects (RAE) of a resistive static contraction of the pelvic depressors (RSCPND) using a Proprioceptive Neuromuscular Facilitation (PNF) pattern in the mid-range of pelvic motion in side-lying as an indirect approach on the improvement of hand-behind-back (HBB) range of motion (ROM) in patients with rotator cuff tears. A static stretch (SS) group and hold-relax (HR) group were used for comparison to the RSCPND group. Twelve outpatients with symptomatic rotator cuff tears were randomly assigned to the RSCPND group, HR group, or SS group. The mean (SD) age was 68.8 (6.2) years (range: 34-81). HBB ROM determined by measuring the distance between the top of the thumb and the spinous process of C7 (TSD) in centimeters was assessed with a tape. Percentage change in TSD after each technique was calculated in comparison with TSD before the technique. Group means were compared using a one-way analysis of variance (ANOVA) with Scheffé’s test. The results of a one-way ANOVA showed significant differences between the techniques. Scheffé’s post hoc testing revealed a significant difference only between the RSCPND group and SS group (p<0.05), reflecting a greater percentage change in TSD in the RSCPND group. Application of RSCPND technique may be an effective approach in indirectly treating extremities that cannot be exercised directly because of pain. RAE of RSCPND technique may improve the AROM of the shoulder joint in patients with rotator cuff tears.

Introduction

The rotator cuff consists of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles together with their tendons. The rotator cuff provides a medial, inferior force to the humeral head during shoulder movements in order to center it in the glenoid fossa, thus providing adequate articular surface stability to allow full range of shoulder movement [1]. Muscle weakness or pain with rotator cuff tears could result in decreased passive range of motion (PROM) and active range of motion (AROM). Prescribed exercises aim to improve PROM, AROM and muscle function by restoring shoulder mobility and stability. In particular, hand-behind-back (HBB) range of motion (ROM) is often used in the evaluation of the effects of the intervention [1, 2]. Restoring HBB ROM, utilizing various physical therapy techniques such as a static stretching (SS) and proprioceptive neuromuscular facilitation (PNF) technique. SS technique is a method in which target muscle is elongated to tolerance (i.e. stretching of the shoulder adductor with external rotator) at the relatively pain-free range and the position held the muscle in the greatest tolerated length [3]. Prolonged tensile stress can improve limited ROM more than can short-duration joint mobilization procedures [4].

A basic PNF technique for increasing AROM of shoulder abduction with internal rotation is the hold-relax (HR) technique utilizing a shortening contraction of the antagonist muscles (i.e. shoulder flexor-adductor-external rotator) on stretch using diagonal position (i.e. shoulder extension-abduction-internal rotation) followed by maximal resistance of static contraction (SC) of the antagonist muscle (i.e. shoulder flexor-adductor-external rotator) [5].
If antagonist muscle contraction is difficult because of pain, we previously found the remote after-effects (RAE) of a resistive SC of the pelvic depressors (RSCPD) using a PNF pattern in the mid-range of pelvic motion in sidelying on the improvement of PROM [5] and AROM of shoulder [7] and knee joints [8] without stretching.

However, previous research has not focused on the effectiveness as the RAE of RSCPD technique compared with the direct approach, such as SS and HR technique in patients with rotator cuff tears. The purpose of this study was to determine the RAE, such as RSCPD technique, on the improvement of HBB ROM in patients with rotator cuff tears.

Materials and Methods

Participants
The source patients consisted of outpatient with rotator cuff tears in a certain hospital from April 2009 to March 2010. Included in study were 12 patients (6 women, 6 men) with the painful movement plus pain in HBB ROM. Eight female and four male outpatients with rotator cuff tears prescribed from orthopedists for improving ROM of the shoulder joint. Exclusion criteria included any other orthopedic disorders and any neurological disorder within the last year that required medical attention. This study was performed in compliance with the revised declaration of Helsinki. All participants gave their written informed consent. The mean (standard deviation; SD) time since onset was 6.8 (8.4) weeks (range 2-26). The mean (SD) age was 68.8 (6.2) years (range 56-79).

Technique
The technique consisted of a RSCPD, HR and SS technique. Twelve outpatients with symptomatic rotator cuff tears were randomly assigned to the RSCPD group, HR group, or SS group. The duration of technique was 20 s in each of the three techniques.

SS technique
Prone on the bed, place the hand of the affected arm behind his/her back at the waistline. An experimenter moved an affected forearm behind his/her back up the spine as high as possible and hold the affected forearm in the greatest tolerated position for 20 s at the relatively pain-free range as shown in fig. 2(a).

HR technique
A maximal SC of the antagonist muscles (shoulder flexor-adductor-external rotator) on stretch using diagonal position (shoulder extension-abduction-internal rotation) is followed by relaxation as shown in fig. 2(b).

RSCPD technique
Resistance was applied by the experimenter. The experimenter stood behind the subject with her elbows locked in extension and placed her hands over the subject’s upper ischial tuberosity as shown in fig. 2(c). The experimenter applied manual resistance over the upper ischial tuberosity in the direction towards the medial sacral crest. The amount of resistance provided by the experimenter was between 2–3 kg according to the strength of the pelvic depressor.

Intrarater reliability was established for the force of RSCPD technique by intraclass correlation coefficient (ICC) for 20 s at random points before the experiment. The value of force as resistance of SCPD was measured by a pinch meter over the ischial tuberosity. The reliability of resistance from 4 trials measured during RSCPD technique was determined by using a two-way analysis of variance (ANOVA) to derive the ICCs. The ICC of the value of the force during RSCPD technique was 0.95 (95% confidence interval [CI] = 0.86-0.99), which reflects a high reproducibility of resistance.

Experimental design

Dependent variable
HBB ROM was determined by measuring the distance between the top of the thumb and the spinous process of C7 (TSD) in centimeters with a tape as shown in fig. 1. Percentage change in TSD after each technique was calculated in comparison with TSD before technique. Percentage change in TSD were compared using a one-way analysis of variance (ANOVA), via the effect of the technique (SS, HR and RSCPD technique).

Data analysis

Statistical Analyses
SPSS for Windows, PASW version 17.0 (SPSS Inc, Tokyo) was used for the analyses. A probability level of P < 0.05 was used to determine statistical significance.

1) Prior to the experimental study, a pilot study was conducted to determine the intratester reliability of the value of TSD. ICC for TSD was calculated [9].

2) The differences in the value of TSD among the three groups were examined using a one-way ANOVA with Scheffé's test.

Results
The ICC (1.1) for TSD was 0.99 ((95% [CI] =0.98 –0.99; p<0.05), which reflects a high reproducibility of TSD. Table 1 shows the mean values and standard deviations for TSD. The mean (SD) percentage change in TSD was 0.01 (3.23) for the SS group, -7.20 (5.04) for the HR group and -8.36 (3.53) for the RSCPD group. A one-way repeated ANOVA for percentage change in TSD showed that the group produced a main effect (p<0.05). Scheffé's
post hoc testing revealed a significant difference only between the RSCPD group and SS group (p<0.05), reflecting a greater percentage change in TSD in the RSCPD group as shown in figure 3.

![Figure 1](image1.png)

**Figure 1.** The minimal distance between the top of a thumb and the spinous process of the seventh cervical (C7) vertebra (TSD) in centimeters
(a) Sitting on the bed, place the hand of the affected arm behind his/her back at the waistline.
(b) Hand-behind-back (HBB) range of motion was measured by having the patient reach behind the back and position the hand as far up the spine as possible with the thumb pointing upwards after technique.

![Figure 2](image2.png)

**Figure 2.** Technique:

a) SS technique; An experimenter moved a affected forearm behind his/her back, up the spine as high as possible and hold the affected forearm in the greatest tolerated position for 20 s at the relatively pain-free range.

b) HR technique; Maximal static contraction of the antagonist muscles (shoulder flexor-adductor-external rotator) on stretch using diagonal position (shoulder extension-abduction-internal rotation) is followed by relaxation.

c) RSCPD technique; An experimenter stood behind the subject with his elbows locked in extension and placed his hands over the subject’s upper ischial tuberosity. The experimenter applied manual resistance over the upper ischial tuberosity in the direction towards the medial sacral crest.
The remote after-effects of a resistive static contraction of the pelvic depressors.....
of posterior depression on the remote muscles. We should investigate the efficient method to induce RAE.

**Conclusion**

Application of RSCPD technique may be effective approach in indirectly treating extremities that can’t be exercised directly because of pain. RAE of RSCPD technique may improve the flexibility and enhance the activation of agonist of the shoulder joint in patients with rotator cuff tears.
