## Introduction

Morphological contrasts based on common body sort or unordinary anatomical shapes have been utilized to recognize and compare among species and bunches. Both truss and classical measurements have been utilized to portray angle body shape. Classical measurements are the foremost utilized in considers of morphometric characteristics of angle [1]. Truss measurements, which incorporate components of body profundity and length along the longitudinal pivot, have hypothetical focal points over classical morphometric characters in dis-criminating among bunches.

Measurements of closely related sets of classical and truss measurements were analyzed to segregate species of *scorpaenidae* counting the dim united rockfish, *Sebastes inermis*, the dark rockfish, and *gobioninae* counting the striped shiner, *Pungtungia herzi*, and the slim shiner, *Pseudopungtungia tenuicorpa*. The estimations of the measurements were bend sin square root changed, and compared as a work of the standard length of each species for factual investigation. For values of the classical measurements of the rockfish, 6 were more prominent for the dim united rockfish than for the dark rockfish, 1 esteem was littler for the previous, and for 2 values there was no measurably critical distinction ( $P > 0.05$ ). For values of the classical measurements of the shiners, 9 values were more prominent for the striped shiner than for the slim shiner, 2 values were littler for the previous, and for 1 esteem there was no measurably critical contrast ( $P > 0.01$ ).

Taxonomically, the dim united rockfish, *Sebastes inermis* has a place to the *Scorpaeniformes* and is an ovoviviparous teleost. It is conveyed all through the oceans of Korea and Southern Hokkaido. It is an financially critical species in coastal situations and is additionally raised in aquaculture. As dull united rockfish is abundant it is conceivable to gather the angle all through the year on the Southern coast of Korea, and it may be a promising species for assets upgrade, counting marine farming [2].

The dark rockfish is additionally ovoviviparous and a part of the Scorpaenidae, and is dispersed all through the Korea, Japan, China and Yellow oceans; in Korean waters it may be a inhabitant coastal angle [3]. The dark rockfish happens all through winter in all coastal waters of Korea since it is huge, shows fast development among rockfish sorts, and is strong to moo temperatures. It is hence an fitting target species for aquaculture and marine farming [4,5].

Striped shiner and slim shiner are one of freshwater angle possessed broadly, and contrasts of morphometric characteristic between striped shiner and slim shiner are not appeared about. In this manner, in this ponder we examined and compared the morphological highlights of these species in Korea, utilizing both classical and truss measurements. The objectives were to recognize those morphometric characteristics that vary essentially between the two Scorpaenidae species, and to evaluate the root of the two shiner species.
